1.1 OVERVIEW

This is a brief guide for converting the subset of Java used in the text into C. The purpose is to help readers who want to implement some algorithms, but prefer to work in C. Alternatively, if a prototype Java implementation has been developed and debugged, readers might wish to convert the program to C to improve its performance. Java has many constructs and features that the text does *not* use, and we do not address their conversion into C.

Familiarity with C is a prerequisite for reading this guide. For excellent treatments of the C language, see Gehani (1998) and Roberts (1995). This guide uses the terminology of "declare" and "define" as set forth by Gehani. On Unix systems, C library functions are documented in the "man pages"; for example, "**man printf**" elicits the specifications for **printf**.

It will also help if Section 1.2, Chapter 2 and the appendix of the text have been looked over (**InputLib** is in the appendix). References in this guide refer to the text. Here are some basic correspondences between Java and C.

Java	*C*
`public static void main(String[] argv)`	`int main(int argc, char* argv[])`
`argv.length`	`argc`
`argv[i]`	`argv[i+1]` (`argv[0]` holds the program name.)
`System.in, System.out, System.err`	`stdin, stdout, stderr`
`print` or `println`	`fprintf` or `printf`

For C code we adopt the convention that *types* and *struct names* begin with a capital letter, but *file names* begin with a lowercase letter, as is most common in C.

1.2 DYNAMIC ALLOCATION: new BECOMES calloc

The **new** operator in Java corresponds most closely to **calloc** in C because **calloc** initializes the allocated memory to binary zeros; **malloc** may also be used. Note that **p** below is technically a pointer in C. However, aside from the "constructor" call to **calloc**, **p** can and should be treated as an array.

Java	*C*
`int[] p = new int[n];`	`int* p = calloc(n, sizeof(int));`
	`int pLength = n;`
`p.length`	`pLength`
`p[i]`	`p[i]`

1.3 ORGANIZER CLASSES BECOME STRUCTS

In general, organizer classes in Java (a term introduced in the text) should be structs in C. Pointers to such structs are not routinely needed, but arrays of structs are appropriate wherever arrays of an organizer class would be used in Java. We illustrate the ideas by translating the **Date** class in Section 1.2 of the text, Exercise 1.1, into C.

```
typedef struct  /* no nested typedefs in C */
     {
     int number;
     int isLeap;  /* no boolean type in C */
     } Year;

typedef struct
     {
     Year year;
     int month;
     int day;
     } Date;

...
Date dueDate, noticeDate;
...
     noticeDate = dueDate;
     noticeDate.day = dueDate.day - 7;
```

In C the assignment statement operates on structs, copying the contents of the struct, not just a reference to it, so the **copy** methods of Java organizer classes are not needed in C. Unlike the Java example in Section 1.2, the above assignments work as expected: Changing **noticeDate.day** does not also change **dueDate.day** because the previous assignment copied the *contents* of **dueDate**, not a reference to it.

It is perfectly proper for a function to return a struct, and this is the recommended way for a function to produce several outputs. Because certain common programming needs are much simpler to code with structs, we would not be surprised to see structs added to some future version of Java, as an extension to the eight built-in primitive types.

1.4 READING INPUT

C offers many—perhaps too many—ways of reading files. Our purpose here is just to sketch the features of C that correspond to the method of reading input described in the appendix of the text, primarily in the class **InputLib**. The C functions involved are all thoroughly documented as part of the **stdio** and **string** libraries. No special library need be defined in C by the programmer. The following includes should be near the beginning of a C file that processes input.

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
```

A *file pointer* (type **FILE ***) is returned by **fopen**, and the standard file pointer **stdin** is automatically available to a C program. Other input functions will use the file pointer as a parameter to indicate which file is to be processed. We will designate the file pointer by **inbuf** in the examples. For example, **fclose(inbuf)** closes a file previously opened by **fopen**.

The primary input function is **fgets**, which gets one complete line of input into a buffer (a character array, previously allocated). It is the analog of **getLine** in **InputLib**. The **getLine** calls in Figure A.2 would translate something like this:

```
char line[1024];  /* A generous overestimate for any one line */
char* fgetsRetn;
...
     fgetsRetn = fgets(line, 1024, inbuf);
     while (fgetsRetn == line)
          {
          Edge e = parseEdge(line);
          ... (see Section 1.4.1 for details)
          fgetsRetn = fgets(line, 1024, inbuf);
          }
     if ( !  feof(inbuf)) { /* Some error occurred */ }
```

Note that **fgets** will not overflow **line** even if the input line is more than 1023 characters, so it is "safe" in this sense.

1.4.1 Parsing a Line of Input

At this point we want to point out that objects in the **String** class in Java are *immutable*; their contents cannot be changed. So each **getLine** call in Java necessarily returns a new string. However, in C **fgets** writes into an array allocated by the caller, and typically this array is used repeatedly for this purpose, as in the example above. Most of the string library functions in C work in a similar fashion; the caller is expected to allocate the space for the result, then use a parameter of the call to inform the string function where that space is. An exception is **strdup**, which allocates the needed space, and returns its address to the caller.

The following table summarizes some correspondences between Java and C. We will see additional details about string library functions later.

Java	*C*
`fp = InputLib.fopen(fname);` [1]	`fp = fopen(fname, "r");`
`line = InputLib.getLine(fp);`	`lPtr = fgets(line, len, fp);`
`Integer.parseInt`	`atoi`
`Double.parseDouble`	`atof`
`String s`	`char s[`n_{const}`]` or `char s[]` or `char* s` (see discussion)
`s.length()`	`strlen(s)`
`toString`	`sprintf`

[1] Assumes **fname** $\neq$ **"-"**.

Since C does not allocate space for strings like Java, the programmer needs to be sure that string operations occur only within allocated space. The library functions **strcpy**, **strcat**, **gets**, and many others are unsafe because they might write beyond the bounds of allocated space. Their counterparts, **strncpy**, **strncat**, **fgets**, include a length parameter to limit the number of characters the function will write. That parameter might be set to any value by the caller, but the sensible value is the number of bytes actually available in the allocated space for the target string.

1.4.2 parseEdge with sscanf

As in the Java version of **parseEdge** in Appendix A of the textbook (see Figure A.3), it is the job of the C version of **parseEdge** to get the data fields out of **line**. First, we typedef **Edge** as a struct, in accordance with the earlier discussion of organizer classes.

```
typedef  struct
     {
     int  from;
     int  to;
     double  weight;
     }  Edge;
```

Now we give a relatively simple version of **parseEdge** in C. It uses the knowledge of what is expected in the input line. A more complicated version in Appendix A.2 outlines a more general tokenizing procedure, to accommodate input strings of unknown format.

The code below uses **sscanf** with parameters that are designed for the line to contain two integers, possibly followed by a floating-point number.

First, we'll give the code, then explain it.

```
Edge  parseEdge(char line[])
     {
     Edge  newE;
     int  numFields;
          numFields = sscanf(line, "%d %d %lf %*s", &newE.from, &newE.to, &newE.weight);
     if (numFields < 2 || numFields > 3)
          {
          printf("Bad edge:  %s", line);
          exit(1);
          }

     if (numFields == 2)
          newE.weight = 0.0;
     return newE;
     }
```

The **sscanf** function extracts data items from the **char** array that is its first parameter (**line** in our example). The extraction is governed by the pattern given in the second parameter, which is usually an explicit string with some percent signs, enclosed in double quotes, as in our example. Remaining parameters are *addresses* at which to store the extracted data items; the "**&**" prefix operator can be read "address of". A full explanation of the **scanf** family may be found in the "**man** pages" of your Unix system, or in many books, or online. We confine our explanation to this example.

The pattern string for extraction includes a space to indicate where an arbitrary number of "white space" characters may occur. A field in this string beginning with "**%**" specifies a data item to be extracted from the input. The codes we use are "**%d**" to extract an "**int**", "**%lf**" to extract a "**double**", and "**%s**" to extract a character string.

But we actually specify "**%*s**" to specify that, although the string is extracted, it is discarded. That is, there is no parameter in the **sscanf** call that specifies a storage location for the string.

So the technique here is a trick to see if there is extra unexpected stuff on the line that was read and passed into **parseEdge**. If **sscanf** *does* find any significant characters after extracting three fields, it will return the value 4; this will lead to an error message.

We emphasize that a field "**%s**" must correspond to a later parameter that gives the address of a **char** array in which to store a string found in **line**. The programmer must ***allocate adequate space*** to store that string.

For most applications where the input is organized by lines, the combination of **fgets** and **sscanf** provides a safe and adequate method to read and parse the input data.

1.5 ADT CLASSES

Although organizer classes should become structs, ADT classes in Java should almost always become pointer types in C. Of course, the pointer type will point to some struct, but that struct will normally be ***hidden from the ADT clients***. The design philosophy is explained in Chapter 2 of the text (see Figure 2.1, e.g.). The *separate compilation* feature of C allows the privacy features of Java to be simulated to a limited extent. We'll walk through an example, using the **IntList** ADT of Chapter 2.

The general idea for a C implementation of an ADT is that the public declarations and definitions go in a "header" file, conventionally named **intList.h**, while the private declarations and definitions go in the file **intList.c**. Both **intList.c** and the ADT client files "include" **intList.h**.

A salient point is that the pointer type for the ADT is normally public (so appears in **intList.h**), while the details of the struct to which it points are private (so appear in **intList.c**). The *name* of the struct (its *tag*) is public, however.

In line with the foregoing remarks, **intList.h** will have a declaration like this near its beginning:

```
typedef  struct IntListStruct * IntList;
```

This *declares* (names, but does not *define*) a struct named **IntListStruct** and defines the type **IntList** to be a pointer to this type of struct, whatever it is.

Now function prototypes and global constants for the ADT may be declared in **intList.h**. Since C does not have classes to qualify function names, it is common to use a prefix to indiocate the type, in this case **int**. Notice that prototypes are very similar to the function headers in Figure 2.4 of the text, but the words **public** and **static** are absent. (The meaning of **static** in C is quite different from its meaning in Java, and is discussed later in this guide.)

```
int  intFirst(IntList L);
IntList  intRest(IntList L);
IntList  Cons(int newElement, IntList oldList);
extern  const  IntList  intNil;
```

A point that is not widely appreciated is that the keyword **extern** in the declaration of **intNil** means that the ***type*** of **intNil** is being declared in this statement, but the actual ***definition*** of **intNil** is elsewhere, ***possibly in the same file or compilation unit***. In this example, **intList.c** will "include" **intList.h** and the above **extern** declaration, and it will also contain the statement that ***defines*** **intNil** (i.e., reserves storage for it). In this way, **intNil** becomes a globally accessible constant. This will be seen in a few paragraphs.

Finally, let us remark that all the documentation (**javadoc**) comments that appear in Figure 2.4 of the text should appear in **intList.h** (as opposed to **intList.c**). The theme of ADT encapsulation and information hiding is that **intList.h** contains the public interface information for the ADT clients, whereas **intList.c** may well not be available to those clients (they would link in the separately compiled **intList.o**).

1.5.1 ADT Implementation File

Now let us turn to the contents of **intList.c**, which *implements* the ADT. After the customary **#include** statements, the first order of business is to complete the declaration of **IntListStruct**. Then **intNil** is defined. Again, it is instructive to compare with Figure 2.4 and observe the correspondences.

```
#include <stdlib.h>
#include "intList.h"

struct IntListStruct
     {
     int element;
     IntList next;
     };

const IntList intNil = NULL;
```

We might also include the following bizarre-looking statement:

```
typedef struct IntListStruct IntListStruct;
```

This makes **IntListStruct** a type as well as the name of a struct. It happens that the **IntList** ADT does not have a use for this type, but it might be convenient in some more elaborate ADTs. Please refer to the C references cited in the overview for more information about this syntactic issue.

The actual C code in the function bodies is quite similar to Java (for the subset of Java used in the main part of the text). A very important difference, however, is that pointer variables are followed by the arrow operator (**->**) in C, not the dot operator, to access instance fields of the object to which they point. Thus the C code will have **L->element**, **L->next**, etc. We include one example.

```
IntList intCons(int newElement, IntList oldList)
{
IntList newList = calloc(1, sizeof(struct IntListStruct));
     newList->element = newElement;
     newList->next = oldList;
     return newList;
}
```

1.6 VISIBILITY OF FUNCTIONS AND DATA STRUCTURES

Although we don't have an example of it in **IntList**, it often happens that we want to define a subroutine or data structure inside an ADT and have it not be visible to the outside world. If nothing else, having every subroutine visible throughout a large program invites name clashes and accidental misuse when a function with a similar name was intended.

The mechanism in C for limiting visibility to the functions that comprise an ADT is to use the **static** keyword. This word is rather misleading, but we are stuck with it in C. When "**static**" appears in front of a declaration or definition that would otherwise be globally visible it directs the compiler and linker to make the name visible only in the current "compilation unit" or file being compiled. Thus by combining **static** and separate compilation, a degree of privacy for an ADT can be achieved. The correspondences between Java and C are as follows:

1. A nonpublic static Java method becomes a static C procedure. Its prototype appears in the .c file, not in the .h file, for the ADT.

2. A public static Java method becomes an extern (globally visible) C procedure or function. Its prototype appears in the .h file and its body appears in the .c file for the ADT.

3. A nonpublic static Java instance field becomes a static C variable. Its definition appears in the .c file, not in the .h file, for the ADT.

4. A public static Java instance field becomes an extern C variable. Its declaration, with the keyword **extern**, appears in the .h file and its definition, without **extern**, appears in the .c file for the ADT.

If these technicalities seem too complicated, readers should remember that limiting visibility is not necessary for correct functioning unless there are name clashes. In most moderate-sized programs, name clashes can be avoided simply by using unique names.

A.1 STORAGE CLASS STATIC

Many of the functions and procedures in Chapter 6, which covers some more advanced data structures, are subroutines that would not appear in the interface of the ADT. That is, they are not themselves ADT operations. These subroutines should be declared as static in C. We will illustrate with one example, from Section 6.7.2, for the **PriorityQ** ADT, whose operations are specified in Section 2.5.1. We assume the header file is **priorityQ.h** and the implementation is in **priorityQ.c**.

Near the beginning of **priorityQ.c**, which uses **pairTree**, the prototype is declared with the reserved word **static**. For example:

```
static Tree pairTree(Tree t1, Tree t2);
```

This declaration is *not* included in **priorityQ.h**.

Somewhere in **priorityQ.c** the function body for **pairTree** is written. For example:

```
static Tree pairTree(Tree t1, Tree t2)
    Tree newTree;
    if (root(t1)->priority < root(t2)->priority)
        newTree = buildTree(root(t1), cons(t2, children(t1)));
    else
        newTree = buildTree(root(t2), cons(t1, children(t2)));
    return newTree;
```

Even if code in a different C file that is compiled together with **priorityQ.c** references a function named **pairTree**, the C linker will not associate it with this function body.

A.2 PARSEEDGE WITH STRTOK_R

The method in this appendix sketches a general method of tokenizing a string, but it is more complicated than is usually needed, and it uses library functions **strtok_r** and **strdup** that are no longer in certain standards. The special compiler flag **-D_SVID_SOURCE** is needed to get their prototypes. **WARNING:** This code is not tested and many problems with **strtok_r** are reported. I suggest you trace carefully with **gdb** to see what addresses are set by **strtok_r** and whether these are in the "heap" or in the "frame stack". Recall that pointers in the "heap" should remain valid until freed, whereas pointers in the "frame stack" become garbage as soon as the procedure in which they are defined returns.

First, we'll give the code, then explain it briefly. As in Section 1.4.2, we typedef **Edge** as a struct, in accordance with the earlier discussion of organizer classes.

```
Edge parseEdge(char line[])
    {
    Edge newE;
    char* strtokState;
    char** savedPtr = & strtokState;
    char* lineTmp = strdup(line);
    char* w1 = strtok_r(lineTmp, " \t\n", savedPtr);
    char* w2 = strtok_r(NULL, " \t\n"), savedPtr;
    char* w3 = strtok_r(NULL, " \t\n"), savedPtr;
    char* w4 = strtok_r(NULL, " \t\n"), savedPtr;

    ... (see Section 1.4.1 for details)
    free(lineTmp);
    free(strtokState);
    return newE;
    }
```

The **nextToken** function in Java translates generally to the **strtok_r** function in the C string library. First we make a new copy of **line** in **lineTmp** because **strtok_r** might change the contents of its first argument. The first call to **strtok_r** requests (the address of) the first "word" or "token" in the **char* lineTmp**. Because **lineTmp** $\neq$ **NULL**,

strtok_r remembers its address in memory allocated by **strtok_r** whose address is stored in **strtokState**. Also **strtok_r** returns the address of the first token. The second through fourth calls to **strtok_r** have **NULL** as the first parameter, indicating that the caller wants subsequent tokens from the same **char*** that it is remembered (somewhere) in memory pointed to by **savedPtr**. Other state might also be saved in this memory, whose layout is not specified in the documentation.

The second parameter of **strtok** specifies a list of characters that are to be treated as delimiters for the token requested. In this case we specified space, tab, and newline, a popular set of delimiters. Extra delimiters are discarded. For example, there might be spaces before the first token.

If no characters remain in **lineTmp** or the only characters that have not been converted to tokens are delimiters, **strtok_r** returns **NULL**.

Whenever **strtok_r** finds the requested token, the returned address is a pointer to a 0-terminated string. We copied **line** into **lineTmp** so **line** would remain intact. If we need to remember the string returned by **strtok** for any length of time, we might need to make a safe copy of it with **strdup**; the documrntation is incomplete on this point. In the example, we use **atoi** and **atof** to interpret these tokens as ints and doubles, after which we do not need them. Then **lineTmp** and **strtokState** can be safely freed so their space can be reused.

Notice that it is not necessary to make a dynamic allocation of the struct **newE** in C; the **return** statement copies its *contents* back into the caller's storage area. Notice how this is different from the construction of an ADT object, as illustrated in the example of **intList.c**.
